

The Effects of Switch Load on Sustained and Transient Costs

Erin Chrystel M. Wright, Alexandria Meyer, & Derek E. Nee

Introduction

Cognitive control, or the ability to guide goaldirected behaviors intentionally, is often assessed by measuring how quickly one can switch from one task or ruleset to another.

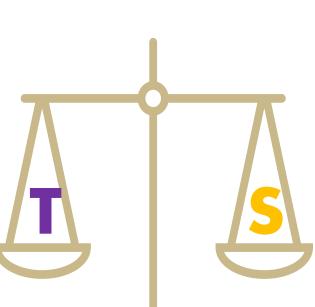

A prevalent model for task switching has been the dual mechanisms of control (DMC) model, which details two control policies proactive and reactive control.

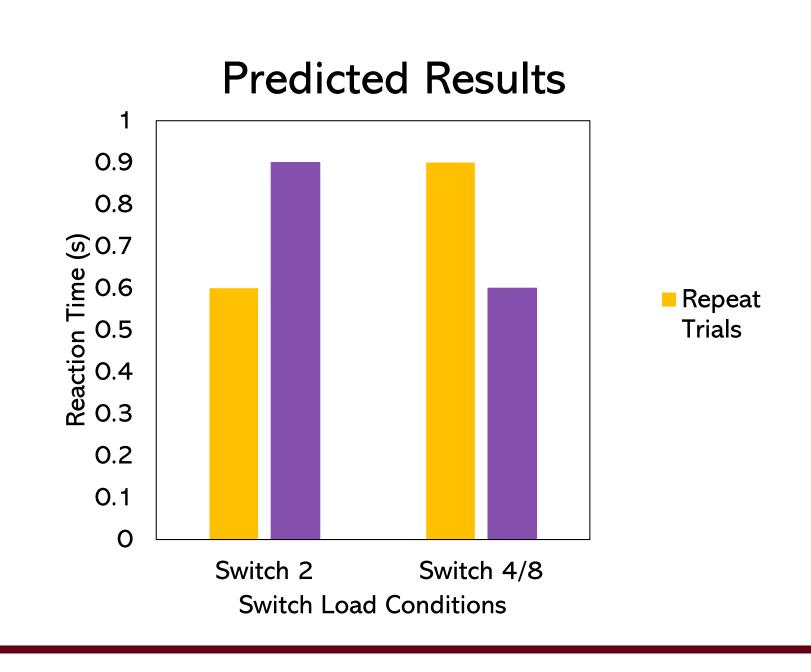

These policies involve two cognitive costs that may exhibit a trade off. The DMC would predict that reactive control would have lower sustained costs and higher transient costs for more efficient task switching in the

moment. Conversely, proactive control would show the opposite for better maintenance of relevant task rulesets.

The aim of this study was to investigate how control costs were influenced by task switching load.

Hypothesis

- During low switch load, it is predicted subjects would use reactive control, showing low sustained and high transient costs.
- During high switch load, it is predicted subjects would use proactive control, showing high sustained and low transient costs.

Methods

DEMOGRAPHICS

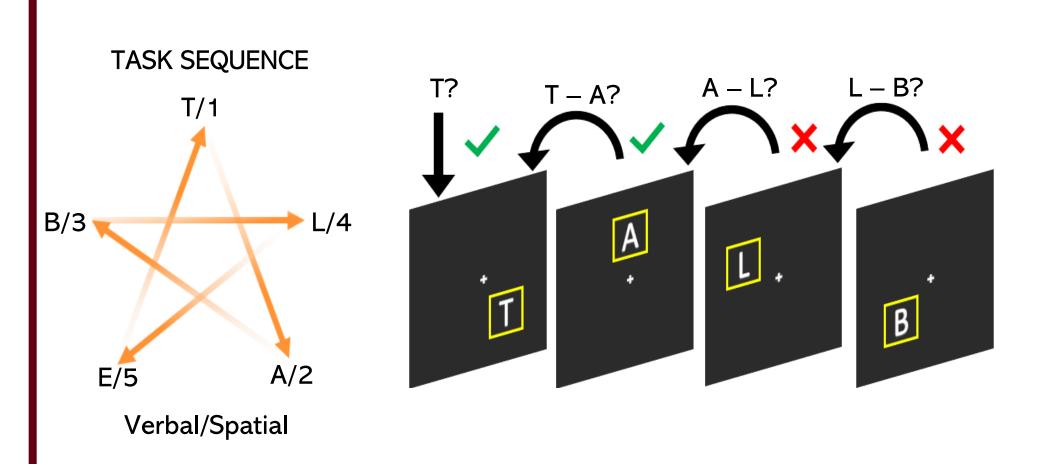

Group 1 Group 2 Task Blocks Task Blocks No Switch Blocks No Switch Blocks Switch 2 Blocks - Switch 2 Blocks Switch 4 Blocks Switch 8 Blocks <u>Demographics</u> | Demographics 6 Female / 2 Male - 3 Female/ 2 Male 8 recruited >> 7 5 recruited >> 5 analyzed analyzed

The main effect of group was not statistically significant in all cases (p > 0.3). To improve power, data was pooled across experiments.

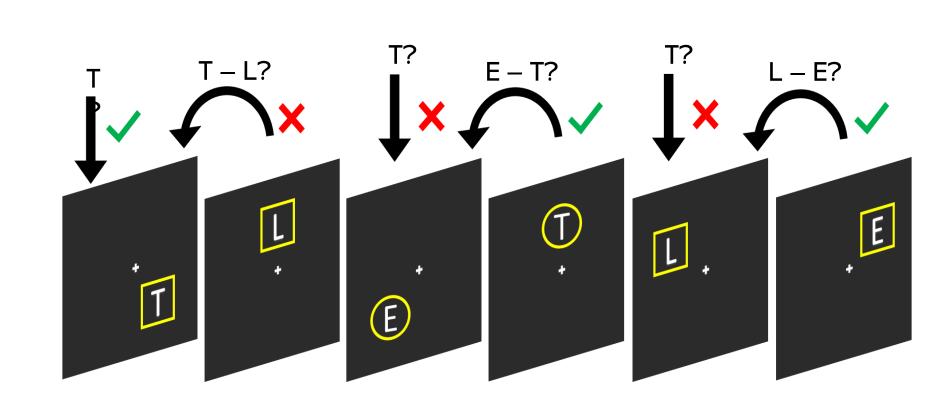

TASKS

Sequence Start \rightarrow Is the current stimulus the beginning of the sequence?

Sequence Back -> Does the current stimulus follow the previous in the sequence?

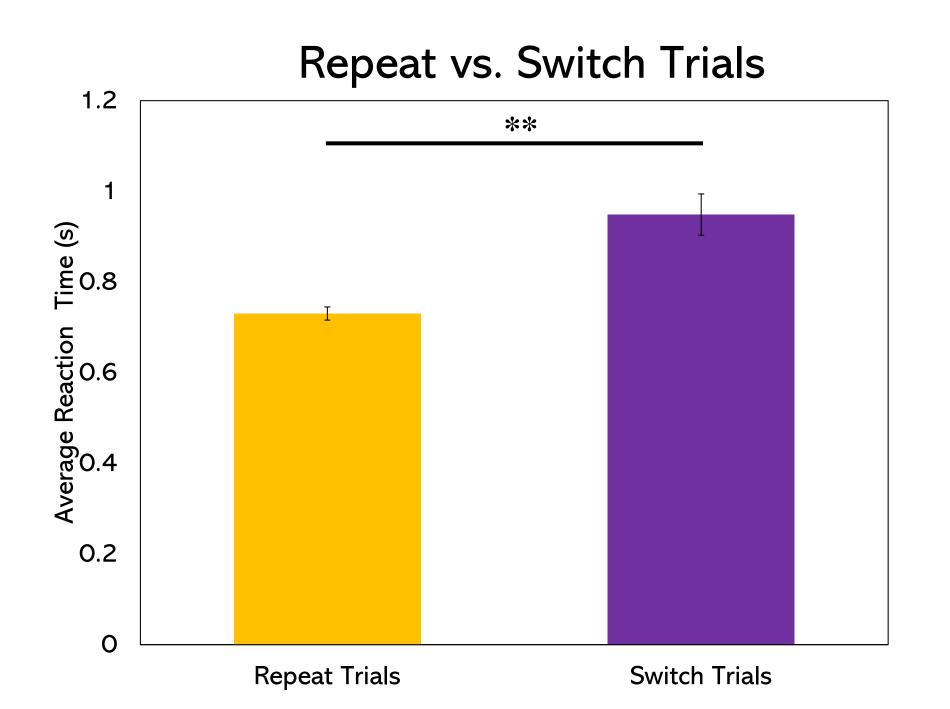

SWITCH -> Is the current stimulus the beginning of the sequence?

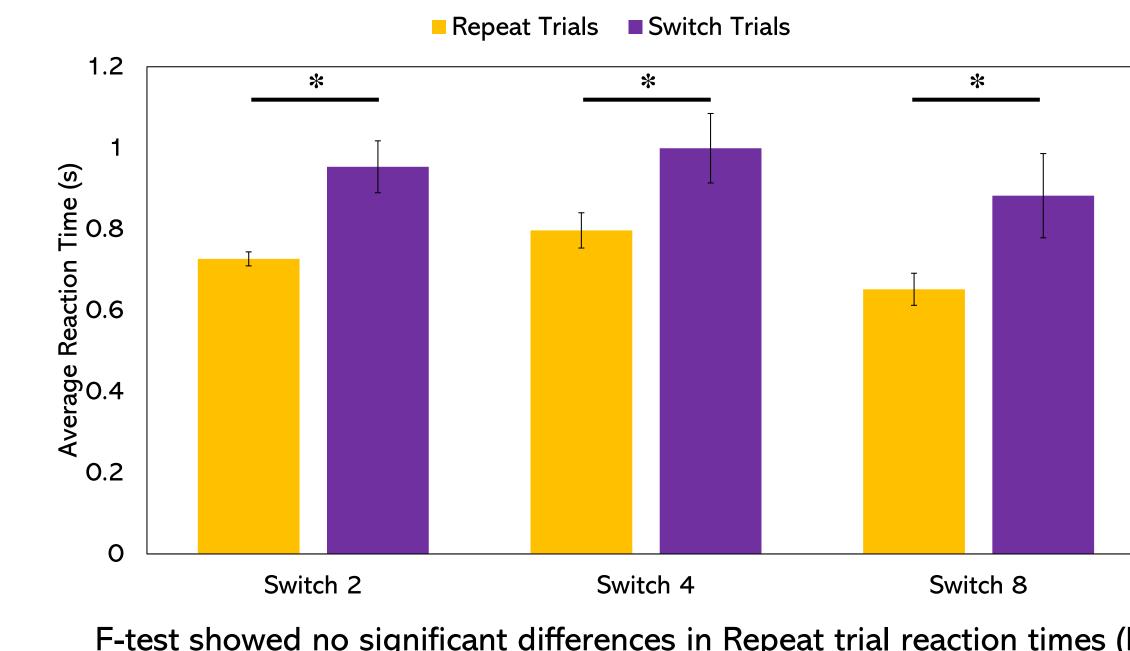

Task switch cued by a change in frame shape.

Results

T-test revealed a significant difference in reaction times between Switch and Repeat Trials (t = -4.46, p > 0.001)

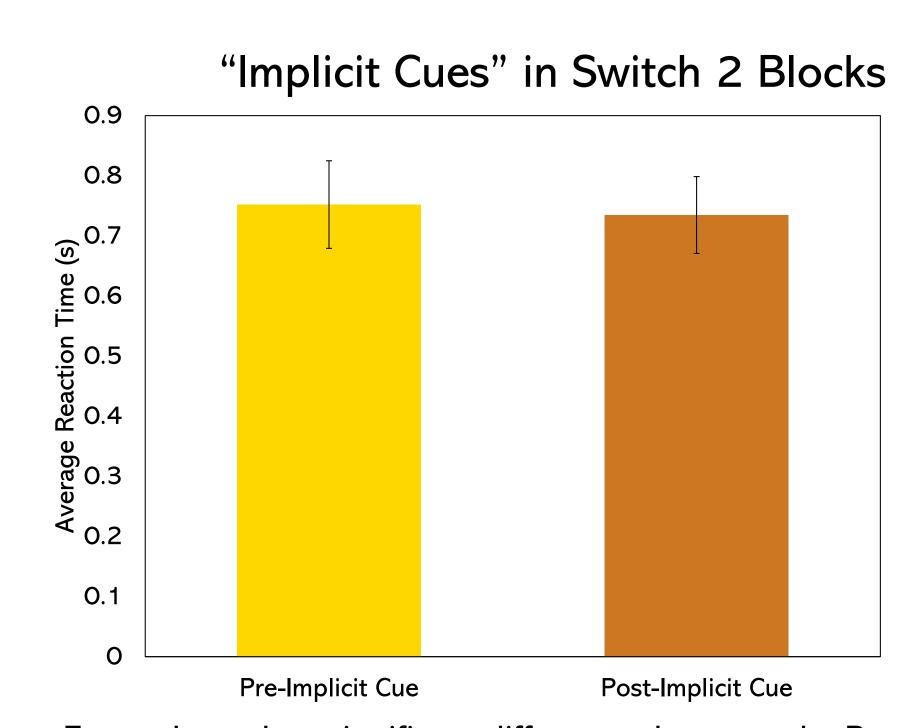

Switch Load Comparisons

F-test showed no significant differences in Repeat trial reaction times (F = 2.20, p = 0.112) and Switch trial reaction times (F = 1.60, p = 0.206) between the switch load conditions.

Pre-Switch vs Post-Switch Trials ■ Pre-Switch Trials ■ Post-Switch Trials 9 O.7 Switch 2 Switch 8 Switch 4

F-test showed no significant difference between the Pre-Switch & Post-Switch repeat trials in all switch load conditions (F = 0.83, p = 0.366)

F-test showed no significant differences between the Pre-Implicit and Post-Implicit Cue repeat trials in Switch 2 Blocks (F = 0.09, p = 0.771)

Conclusions

- Although sustained and transient costs are present, they remained stable regardless of switch load condition. This could suggest no cost trade-off between the control policies. It could also be subjects used the same policy regardless of switch load.
- Results also show no differences in behavior before or after a switch occurs, suggesting a consistent cost demand level in all trials. This was the case for all switch load conditions, suggesting consistent control policy use.
- Signs of implicit cuing for a possible switch were not present in low switch conditions. As subjects were not explicitly cued to which block type they were in, this may suggest subjects were not anticipating switch trials.
- FUTURE DIRECTION: Currently collecting new dataset with Switch 0/2/4/8 Blocks all in one paradigm. May also include exogenous cuing in a future paradigm.
